Problem Set #2: Supervised Learning II

Problem 1 Logistic Regression: Training stability

- (a) The most notable difference in training the logistic regression model on datasets A and B is that the algorithm does not converge on dataset B.
- (b) To investigate why the training procedure behaves unexpectedly on dataset B, but not on A, we print the value of θ after every 10000 iterations. We notice that for data set B, although the normalized $\frac{\theta}{\|\theta\|}$ almost stop changing after several tens of thousands of iterations, each component of the unnormalized θ keeps increasing. We also notice that dataset A is not linearly separable while dataset B is linearly separable.

From the code, we notice that the algorithm calculates the gradient of loss function as

$$\nabla_{\theta} J(\theta) = -\frac{1}{m} \sum_{i=1}^{m} \frac{y^{(i)} x^{(i)}}{1 + \exp(y^{(i)} \theta^{T} x^{(i)})}.$$

From this, we know that the algorithm uses gradient descent to minimize the loss function

$$J(\theta) = -\frac{1}{m} \sum_{i=1}^{m} \log \frac{1}{1 + \exp(-y^{(i)}\theta^{T}x^{(i)})}.$$

Hence, for a dataset that is linearly separable, that is, $y^{(i)}\theta^Tx^{(i)} > 0$ for all i, a θ with larger norm always leads to a smaller loss, preventing the algorithm from converging. However, on a dataset that is not linearly separable, there exists i such that $y^{(i)}\theta^Tx^{(i)} < 0$. By plotting $f(z) = \log(1 + e^{-z})$ in Figure 1, we notice that negative margin dominates when scaling θ to a larger norm. Hence, we cannot always increase θ to a larger norm while minimizing $J(\theta)$.

- (c) Consider the following modifications
 - i. Using a different constant learning rate will not make the algorithm converge on dataset B, since scaling θ to larger norm still always decreases the loss.
 - ii. Decreasing the learning rate over time will make the algorithm converge for dataset B, since in this way the change of θ converge to 0.

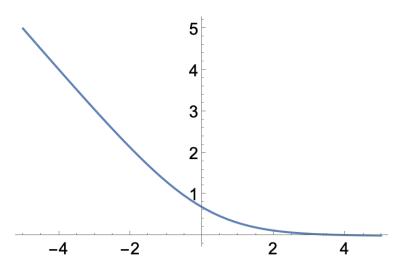

Figure 1: Plot of $f(z) = \log(1 + e^{-z})$ for $-5 \le z \le 5$.

- iii. Linear scaling the input features does not help, since it does not change the dataset's linear separability.
- iv. Adding a regularization term $\|\theta\|_2^2$ helps, since now scaling θ to larger norm penalize the algorithm.
- v. Adding zero-mean Gaussian noise to the training data or labels helps as long as it makes the dataset not linearly separable.
- (d) Support vector machines, which uses hinge loss, are not vulnerable to datasets like B. In SVM, geometric margin is considered, instead of functional margin considered here. In other words, θ is normalized, so for linearly separable datasets like B, the algorithm will still converge.

-

Problem 2 Model Calibration

Try to understand the output $h_{\theta}(x)$ of the hypothesis function of a logistic regression model, in particular why we might treat the output as a probability.

When probabilities outputted by a model match empirical observation, the model is well-calibrated. For example, if a set of examples $x^{(i)}$ for which $h_{\theta}(x^{(i)}) \approx 0.7$, around 70% of those examples should have positive labels. In a well-calibrated model, this property holds true at every probability value.

Suppose training set $\{x^{(i)}, y^{(i)}\}_{i=1}^m$ with $x^{(i)} \in \mathbb{R}^{n+1}$ and $y^{(i)} \in \{0, 1\}$. Assume we have an intercept term $x_0^{(i)} = 1$ for all i. Let θ be the maximum likelihood parameters learned after training logistic regression model. In order for model to be well-calibrated, given any range of probabilities (a, b) such that $0 \le a < b \le 1$, and trianing examples $x^{(i)}$ where the model outputs $h_{\theta}(x^{(i)})$ fall in the range (a, b), the fraction of positives in that set of examples should be equal to the average of the model outputs for those examples. That is,

$$\frac{\sum_{i \in I_{a,b}} P(y^{(i)} = 1 \mid x^{(i)}; \theta)}{|\{i \in I_{a,b}\}|} = \frac{\sum_{i \in I_{a,b}} \mathbb{I}\{y^{(i)} = 1\}}{|\{i \in I_{a,b}\}|},$$

where
$$P(y^{(i)} = 1 \mid x; \theta) = h_{\theta}(x) = 1/(1 + \exp(-\theta^T x)), I_{a,b} = \{i : h_{\theta}(x^{(i)}) \in (a,b)\}.$$

(a) For the described logistic regression model over the range (a, b) = (0, 1), we want to show the above equality holds. Recall the gradient of log-likelihood

$$\frac{\partial \ell}{\partial \theta_j} = \sum_{i=1}^m (y^{(i)} - h_{\theta}(x^{(i)})) x_j^{(i)}.$$

For a maximum likelihood estimation, $\frac{\partial \ell}{\partial \theta} = 0$. Hence $\frac{\partial \ell}{\partial \theta_0} = 0$. Since $x_0^{(i)} = 1$, we have

$$\sum_{i=1}^{m} y^{(i)} - h_{\theta}(x^{(i)}) = 0.$$

The desired equality follows immediately since $i \in I_{0,1}$ for all i.

(b) A perfectly calibrated model — that is, the equality holds for any $(a, b) \subset [0, 1]$ — does not imply that the model achieves perfect accuracy. Consider $(a, b) = (\frac{1}{2}, 1)$, the above equality implies

$$\frac{\sum_{i \in I_{a,b}} P(y^{(i)} = 1 \mid x^{(i)}; \theta)}{|\{i \in I_{a,b}\}|} = \frac{\sum_{i \in I_{a,b}} \mathbb{I}\{y^{(i)} = 1\}}{|\{i \in I_{a,b}\}|} < 1.$$

This shows that the model does not have perfect accuracy.

For the converse direction, a perfect accuracy does not imply perfectly calibrated. Consider again $(a,b)=(\frac{1}{2},1)$, then we have

$$\frac{\sum_{i \in I_{a,b}} \mathbb{I}\{y^{(i)} = 1\}}{|\{i \in I_{a,b}\}|} = 1 > \frac{\sum_{i \in I_{a,b}} P(y^{(i)} = 1 \mid x^{(i)}; \theta)}{|\{i \in I_{a,b}\}|}.$$

(c) Discuss what effect of L_2 regularization in the logistic regression objective has on model calibration. For L_2 regularization in logistic regression, the gradient becomes

$$\frac{\partial \ell}{\partial \theta_j} \sum_{i=1}^m (y^{(i)} - h_{\theta}(x^{(i)})) x_j^{(i)} + 2C\theta_j = 0.$$

Hence, the equality does not hold unless $\theta_0 = 0$.

The interval (0,1) is the only range for which logistic regression is guaranteed to be calibrated. When GLM assumptions hold, all ranges $(a,b) \subset [0,1]$ are well calibrated. In addition, when test set has same distribution and when model has not overfit or underfit, logistic regression are well-calibrated on test data as well. Thus logistic regression is popular when we are interested in level of uncertainty in the model output.

Problem 3 Bayesian Interpretation of Regularization
